Objective: To perform a systematic review of exercise trials post stroke.

Design: A systematic review of controlled clinical trials.

Search strategy: MEDLINE, EMBASE, CINAHL, Amed, Sports Discus, Cochrane controlled trials register and PEDro were searched for relevant trials.

Inclusion criteria: Studies – randomized or quasi-randomized controlled clinical trials. Participants – Adults of any age with a clinical diagnosis of stroke. Interventions – Any cardiovascular exercise intervention aimed at improving cardiovascular fitness and/or function.

Data collection and analysis: Two independent reviewers categorized selected trials, documented the methodological quality and extracted the relevant data. Comparisons of cardiovascular exercise interventions versus no cardiovascular intervention were made. Statistical comparisons were carried out using a random effects model to calculate standardized mean differences.

Results: We identified three eligible trials. Small numbers and heterogeneous outcomes limited the analyses and comparisons. Based on the limited data available, we found that cardiovascular exercise post stroke was no better than no exercise with respect to disability, impairment, extended activities of daily living, quality of life and death.

Conclusion: Insufficient evidence was identified to establish if cardiovascular exercise has a positive effect on disability, impairment, extended activities of daily living, quality of life and case fatality post stroke.

Introduction

Survivors of stroke often have poor exercise capacity.1,2 Although this may in part be due to the normal ageing process,3 the exercise capacity of stroke patients has been found to be approximately 40% below that of age- and gender-adjusted norms for sedentary individuals.4 Stroke patients often have reduced mobility, and a reduction in exercise capacity can occur secondary to immobility.5 The energy expenditure required by patients with stroke to carry out daily functions, such as walking, is significantly greater than the normal
energy expenditure for these tasks. Hence limited exercise capacity is likely to further disable stroke patients in their ability to carry out routine functional tasks and extended activities of daily living. Furthermore, the documented reduction in cardiovascular fitness may contribute to the increased risk of further stroke or myocardial infarction that stroke patients have in comparison with normal subjects. Exercise has been proven to be beneficial post myocardial infarction in terms of reduction death and increasing revascularization. Epidemiological studies suggest that up to 70% of stroke patients have some form of coexisting heart disease.

The documented reduction in cardiovascular fitness leads to the hypothesis that cardiovascular training could be beneficial to patients following stroke. However, physical rehabilitation post stroke has tended to concentrate on improving quality of movement and function in reduction of disability and cardiovascular training is not currently a routine part of the process of stroke rehabilitation. Further investigation is essential to determine whether cardiovascular exercise training could benefit stroke patients in terms of impairment and handicap, and whether it should be a routine component of the rehabilitation process.

We carried out a systematic literature review of randomized and quasi-randomized controlled trials in order to determine the effects of cardiovascular exercise training on selected outcomes.

**Methods**

Extensive literature searching was carried out to identify controlled clinical trials (randomized and quasi-randomized) of cardiovascular exercise post stroke. MEDLINE, EMBASE, CINAHL, Amed, Sports Discus, Pedro and the Cochrane controlled trials register were searched from 1985 until October 2001, using key words relating to stroke combined with key words relating to the possible interventions (‘exercise therapy’, ‘exercise’, ‘rehabilitation’, ‘sports medicine’, ‘sports medicine mp’, ‘physical fitness’, ‘class$.tw’, ‘strength$.tw’, ‘train$.tw’).

The full search strategy is available from the authors. The reference lists of all trials found using the search were searched for any relevant trials.

**Identification of relevant trials**

One reviewer read the titles of the identified references and eliminated obviously irrelevant studies. The abstracts of the remaining studies were obtained and, based on the inclusion criteria (Table 1), one reviewer ranked these as relevant, irrelevant or unsure. A second reviewer then independently ranked these trials using the same method. Any disagreements were resolved through discussion between the reviewers.

Two independent reviewers documented the methodological quality of studies and extracted relevant data. The following quality criteria were documented: randomization (allocation concealment); baseline comparison of groups; blinding of subjects and providers of care to treatment group; blinding of outcome assessor; reliability of outcome measures; possibility of contamination/cointervention by therapists providing intervention; completeness of follow-up; other potential confounders.

Data extraction was undertaken to document where possible: trial setting (i.e., hospital, community); details of participants (i.e., age, gender, side of hemiplegia, stroke classification, comorbid conditions, premorbid disability); inclusion and exclusion criteria; all assessed outcomes. Authors were contacted for clarification, or to provide missing data, where necessary.

**Analysis**

Comparisons were planned as cardiovascular exercise intervention versus (a) no intervention, (b) placebo exercise, (c) usual care. In addition, a number of subgroup analyses were planned to determine the relative efficacy of the various types of cardiovascular exercise (e.g., cycle ergometer, one-to-one exercise, treadmill training) and the effects of training in relation to length of time since stroke.

All outcomes analysed were presented as continuous data. Standardized mean differences and 95% confidence intervals were calculated using a random effects model.
of relevant outcome measures, Table 4 illustrates the outcome measures for which data could be extracted.

The large number of heterogeneous outcome measures reported made it impossible to analyse all the documented data, and limited the potential for combination and comparison of outcome measures. There were insufficient data to carry out the preplanned subgroup analyses.

Data from Teixeira-Salmela et al.\textsuperscript{26} and Duncan et al.\textsuperscript{27} could be combined within meta-analysis for gait speed, extended activities of daily living (ADL) and quality of life outcomes; data from Potempa et al.\textsuperscript{28} and Duncan et al.\textsuperscript{27} could be combined within a meta-analysis for the functional independence outcomes. These analyses demonstrated that there were no significant differences between patients carrying out cardiovascular exercise and those not carrying out cardiovascular exercise. Standardized mean difference and 95% confidence intervals for each outcome are displayed in Table 4.

Although the meta-analyses demonstrated no significant differences between the outcomes of patients who did or did not carry out cardiovascular exercise, a number of statistically significant effects were reported in the results of the three individual trials. Teixeira-Salmela et al.\textsuperscript{26}
reported statistically significantly positive effects of cardiovascular training for all assessed outcomes (gait speed, stair climbing, human activity profile, Nottingham health profile and isokinetic strength) in the intervention group ($p < 0.01$); Duncan et al.\(^7\) found significant improvements in motor function ($p < 0.01$) and gait velocity ($p < 0.05$); Potempa et al.\(^8\) found significant improvements in $V_{CO_2}$ ($p = 0.01$), $VO_2$, workload and exercise time ($p = 0.0001$). Potempa et al.\(^8\) also reported that a significant correlation existed between increase in $VO_2$ max and motor function.

### Discussion

This review could not identify compelling evidence that cardiovascular exercise is beneficial to outcome following stroke. However it must be stressed that no evidence of effect is different from evidence of no effect.

Only three small studies met inclusion criteria, providing data from only 75 patients. Use of a large number of heterogeneous outcome measures limited the ability to combine results in meta-analyses. Although the results from the three individual studies do provide encouraging

evidence that cardiovascular training may be able to improve outcomes in patients with stroke, this evidence is derived from very small numbers of patients carrying out a variety of different exercise programmes, in studies with possible methodological limitations. Further research is required to address the effectiveness of cardiovascular exercise in stroke patients. Poor methodological quality led to the exclusion of a number of studies, and a lack of reported details (e.g., method of randomization, blinding or assessors, patients and therapists) makes it difficult to fully assess the quality of the included trials. A further limitation of all of the

included studies was the failure to include a long-term (i.e., six months to one year) follow-up to enable assessment of the maintenance of any changes in outcome. Future studies should be careful to address these important areas of methodological quality in order to reduce the potential for the introduction of bias. Any systematic review/meta-analysis is reliant on the quantity and quality of trial data identified. Although the lack of trials identified prevents this review from reaching any clear conclusions regarding the efficacy of cardiovascular exercise

Clinical messages

- There is currently insufficient evidence from controlled clinical trials to conclude that cardiovascular exercise is beneficial for improving outcome following stroke.
- There is an urgent need for further trials to investigate the efficacy of cardiovascular exercise following stroke.

in patients with stroke, this should in no way diminish the importance of this research question or the results of this review.

The efficacy of cardiovascular exercise post stroke remains a clinically important question in terms of a patient’s function, exercise capacity, quality of life and risk of future vascular events. This review indicates the need for more, high-quality, randomized controlled trials into the effects of cardiovascular exercise post stroke.

Conclusions

We could not identify evidence from randomized trials to confirm or refute the efficacy of cardiovascular exercise post stroke. Individual studies of cardiovascular exercise post stroke show significant improvements in impairment\(^{26–28}\) and quality of life.\(^{26}\) Further research is needed in this important area of stroke rehabilitation.

Future studies should ensure that they clearly define and monitor what is meant by ‘cardiovascular exercise’ and concentrate on the effects of cardiovascular exercise on function, quality of life and exercise capacity.
